

THE ESTIMATION OF MARGINAL UTILITY OF INCOME
FOR APPLICATION TO AGRICULTURAL POLICY ANALYSIS

BY

E. NEAL BLUE AND LUTHER TWEETEN*

*Respectively Research Associate and Anderson Professor, Department of Agricultural Economics and Rural Sociology, The Ohio State University, Columbus Ohio.

THE ESTIMATION OF MARGINAL UTILITY OF INCOME FOR APPLICATION TO AGRICULTURAL POLICY ANALYSIS

The paradigm of utility maximization is the core of demand and social welfare theory. Marshallian demand and supply measurement, though based on utility maximization, has evolved explicitly accounting for the fact that utility is not measurable per se (see Pollack and Wales). The perception that utility is subjective and buried in the psyche has restrained social scientists from directly estimating utility, however this may be accomplished. Although social welfare theory holds that interpersonal utilities are not comparable, the use of aggregate economic measures such as the gross domestic product (GDP) as a basis for policy analysis belies that assertion. By assuming that more GDP is good (without regard to its distribution), policymakers make the value judgment that a dollar of income not only contributes to well being, but also that well-being is enhanced equally whether dollars are accrued by poor or wealthy individuals.

The perceived inability to measure utility has not hindered economists from making statements about marginal utility in applied economics. The new welfare economics paradigm used by neoclassical economists divides economics into equity (wealth and income distribution issues) and efficiency (input/output). Applied mainstream economists have emphasized the efficiency dimension and discarded the equity criterion. Many radical economists and other social scientists have held that equity is the most important dimension of economics and have rendered to economic

efficiency the same obscurity that neoclassical economists have rendered to equity.

The motives of those emphasizing either equity or efficiency are not in doubt. Both groups are concerned about the well-being of people. Neoclassical economists implicitly assume that the marginal utility of income is constant per dollar and equal for everyone so that maximizing efficiency maximizes utility. On the other hand, social scientists who emphasize equity implicitly assume individuals are sufficiently efficient, motivated, and social-minded so that market incentives are not of consequence for the general welfare. Both positions have elements of truth and error.

Improved estimates of marginal utility of income can help bridge the gap between equity and efficiency in economics. Such measures are required to assess the impact on the general welfare of public policies influencing the level and distribution of wealth. Measures of utility are also important to predict risk avoidance or preference behavior of farmers and others. Measures of utility can help economists to develop farm enterprise plans that farmers are likely to adopt to increase their level of satisfaction. In the public policy arena, measures of marginal utility can help to determine whether people are better off from a revision in income tax rates, from income transfer programs, or from a resource development project (based on its utility-weighted cost-benefit ratio).

Social indicators providing insights into diverse relationships that determine well being of society are available and helpful. However, because social indicators lack a common unit of measurement (such as money used to aggregate economic indicators

into economic accounts), they have not been aggregated into a workable system of social accounts, despite valiant proposals to do so by Karl Fox and others.

The objective of this study is to construct a quality of life index that approximates utility from empirically measured socio-psychological indicators of well-being. A secondary objective is to determine whether aggregation weighted by factor analysis is measurably superior to aggregation by simple summation of socio-psychological indicator variables to form a quality of life index. The constructed quality of life index is intended for group rather than interpersonal comparisons of well-being. Thus the index is better suited for policy analysis than for microeconomic analysis.

The Estimation of Marginal Utility

The empirical estimation of marginal utility (MU) has proceeded along two distinct lines. The first is via the standard gamble technique using the von Neumann-Morgenstern approach. The second approach is to estimate MU by using social-psychological measures of well-being taken from personal interviews.

In the standard gamble technique, individual utility functions are traced out from data obtained from personal interviews where the respondent specifies preferred choices from sets of alternative payoffs and probabilities (see Halter and Mason; Hildreth and Knowles; Lin, Dean, and Moore). The disadvantages of this approach are (1) small

non-random samples arising from heavy respondent burden and difficult questionnaires, (2) the confounding of utility and gaming effects so that utility derived out of additional income *per se* cannot be disentangled from utility derived out of taking risks for monetary gain, and (3) and the persistent violations of the expected utility axioms as shown in the literature (see Shoemaker).

In the second or socio-psychological survey approach, personal measures of well-being are employed to estimate MU (see Harper and Tweeten; Tweeten and Mlay). In 1980 Tweeten and Mlay used factor-weighted and simple-summation aggregation to construct a direct measure of utility from social-psychological indicator variables found in the *General Social Surveys*. This report extends the framework of Tweeten and Mlay beyond the quadratic utility function to include various functional forms. In addition, more years of data are used to increase the reliability of estimates and allow tests for the intertemporal stability of marginal utility.

Even with properly validated indicator variables, the socio-psychological approach poses at least two problems. First, the survey instrument measures the subjective or perceived well-being rather than actual utility. Second, agreement among social scientists is incomplete regarding domains of life and their weights in measuring well-being.

Regarding the first problem, individual responses to the socio-psychological attitudinal scales may be subjective but the analysis converting individual responses into an overall utility measure for groups can be objective. Although imprecise, the

estimates derived in this study using objective scientific procedures are likely to be an improvement over value judgments by politicians of the marginal utility of income.

Measurable domains of life experience must be used in constructing a quality of life index as a proxy for utility. Tweeten and Mlay proposed the following candidates for domains or subindices (for further discussion, see Coughenour and Tweeten).

Hedonistic Subindex: Feelings of happiness or excitement with life. Reflects feelings (emotions) as opposed to cognitive (knowing, rational) dimensions of well-being. This subindex is represented by two indicator variables from the *General Social Surveys* (Table 1).

Anomie Subindex: Lack of confidence in one's social environment. Anomie, a concept originating with Emile Durkheim to refer to normlessness, is characterized by feelings of fatalism, alienation, pessimism, and demoralization. Anomie is represented by six indicator variables from the *General Social Surveys* (Table 1).

Confidence Subindex: Confidence in persons running institutions such as the educational system, government, business, labor unions, media, and the like. This subindex is represented by 14 indicator variables from the *General Social Surveys* (Table 1).

Satisfaction Subindex: Degree of satisfaction with various aspects of life including family life, marriage, neighborhood, community (city),

job, friendships, and the like. Six indicator variables forming this subindex are listed in Table 1.

It is apparent that perceived quality of life may differ from study to study depending on: (1) the subindices involved, (2) the indicator variables in each of the subindices, (3) method of aggregation, and (4) the sample of respondents. However, an earlier study (Tweeten and Mlay) found that the quality of life index was quite robust with respect to changes in domains and samples.

The Creation of the Quality of Life Index

Twenty-eight indicator variables shown in Table 1 are aggregated into a single dependent variable, the quality of life index, using two methods: simple-summation and factor-weighted aggregation. The resulting index is then regressed on a group of explanatory variables including age, income, and education. The justification for the inclusion of the independent variables is discussed in the next section.

The data for this study are from personal interview surveys conducted in selected years from 1976 to 1990 (see Table 2) by the National Opinion Research Center (NORC), and described in the *General Social Surveys, 1972-1993*. Each survey was an independently drawn random sample of English speaking persons 18 years of age or over living in non-institutional arrangements within the continental United States. Sample size is 5,259.

The component indicator variables used to construct the quality of life index are categorized under the domains defined in the previous section. Indicator variables were chosen for their conceptual relevance and their availability. The coding for each of the indicator variables is shown in the *General Social Surveys* and Tweeten and Mlay. Factor analysis was used to construct a quality of life index from the indicator variables. The Statistical Analysis System (SAS) v. 6.13 package was used to perform the computations.

Table 1 shows the results of the factor analysis used to group indicator variables into a single quality of life index. If the subindices comprise distinct domains of the quality of life, each factor in Table 1 will be uniquely and prominently identified with a subindex. The indicator variables associated with the Hedonistic and Satisfaction subindices load most heavily on Factor 1. The Anomie 1 and Anomie 2 subindices load heavily on Factor 4 and Factor 3, respectively.

The confidence subindex appears to be multidimensional because no one factor figures prominently for all indicator variables comprising the confidence subindex. For factor 2, weights are large for the indicator variables measuring confidence in financial institutions (CONFINAN), business (CONBUS), religion (CONCLERG), education (CONEDUC), the executive branch of the federal government (CONFED), medicine (CONMEDIC), the U.S. Congress (CONLEGIS), and the military (CONARMY). The only variable prominent in factor 3 is confidence in the U.S. Supreme Court (CONJUDGE). The indicator variables for confidence in labor (CONLABOR),

confidence in the press (CONPRESS), and confidence in the TV media (CONTV) load most heavily into factor 5. The confidence in science (CONSCI) and the perception that one is getting ahead in life (GETAHEAD) weigh most heavily in Factor 6. Only the six factors with eigenvalues exceeding 1.0 were included.

The Quality of Life Index (QLI) constructed from the results of the factor analysis in Table 1 is:

$$(1) \quad QLI = \sum_{i=1}^N \sum_{j=1}^M w_j a_{ij} x_i$$

where: w_j = eigenvalue associated with factor j ,
 a_{ij} = factor loading of indicator i in factor j ,
 x_i = normalized indicator variable i , $x_i = (X_i - \bar{X}_i)/s_i$ where the original observations X_i are adjusted for the estimated mean \bar{X}_i and standard deviation s_i .

A common, alternative method of aggregating indicator variables is the simple summation:

$$(2) \quad QLI' = \sum_{i=1}^N x_i .$$

Conceptually, the factor-weighted aggregation method shown in equation 1 is preferred. This method emphasizes indicator variables prominent in factors explaining the greatest proportions of overall variance in the indicator variables. Operationally, however, the simple-summation aggregation method shown in equation 2 is preferred for simplicity and convenience.

Justification for Independent Variable Selection

Table 3 lists independent variables used to account for the variation in the dependent variable QLI or QLI'. Given that one of the major objectives of this study is to estimate the marginal utility of income, income becomes a primary variable used in explaining the variation of QLI and QLI'. Demographic variables are included as controls because of expected systematic differences in marginal utility among individuals with different demographic characteristics (see Pollack and Wales).

An occupational prestige variable is included to control for social standing arising from the practice of a particular occupation. The absence of the prestige variable could confound the influence of income with prestige and hence bias the coefficients of the income variable in the QLI equation.

An alternative approach would be to measure the marginal utility of wealth (net worth) rather than income. Data on human and material wealth of respondents participating in the *General Social Surveys* are not available. However, income is a

useful proxy because it is the flow from the stock of wealth and is perfectly correlated with wealth if rates of return on wealth are equal for all respondents.

Econometric Analysis and Results

Econometric analysis is performed to determine the contribution of independent variables to variation in the quality of life index. Several functional forms are used to satisfy alternative concepts of how utility is influenced by changes in income. In addition, the factor-weighted (QLI) and simple-summation weighted (QLI') quality of life indices are alternatively used as dependent variables to determine if the econometric results are invariant with respect to the construction of the quality of life index.

The functional forms investigated are the quadratic, Cobb Douglas, square root, and semilog equations. These are shown, respectively, as follows (See Table 3 for variable definitions):

$$(3) \quad QLI = \beta_0 + \beta_1 \text{Income} + \beta_2 \text{Income}^2 + \beta_3 \text{Ageclass} + \beta_4 \text{Ageclass}^2 + \beta_5 \text{Prestige} + \beta_6 \text{Education} + \beta_7 \text{Size} + \beta_8 \text{Farmer*Income} + \sum \delta_i X_i$$

$$(4) \quad QLI = \exp(\beta^0 * \text{Income}^{\beta^1} * \text{Ageclass}^{\beta^2} * \text{Prestige}^{\beta^3} * \text{Education}^{\beta^4} * \text{Size}^{\beta^5}) * \exp(\sum \delta_i X_i)$$

$$(5) \quad \text{QLI} = \beta_0 + \beta_1 \text{Income} + \beta_2 \text{Income}^{0.5} + \beta_3 \text{Ageclass} + \beta_4 \text{Ageclass}^2 + \beta_5 \text{Prestige} + \beta_6 \text{Education} + \beta_7 \text{Size} + \beta_8 \text{Farmer*Income} + \Sigma \delta_i X_i$$

$$(6) \quad \text{QLI} = \beta_0 + \beta_1 \ln(\text{Income}) + \beta_2 \text{Income}^2 + \beta_3 \text{Ageclass} + \beta_4 \text{Ageclass}^2 + \beta_5 \text{Prestige} + \beta_6 \text{Education} + \beta_7 \text{Size} + \beta_8 \text{Farmer*Income} + \Sigma \delta_i X_i$$

Here $\Sigma \delta_i X_i = \delta_1 \text{Health} + \delta_2 \text{Male} + \delta_3 \text{Unemployed} + \delta_4 \text{Married} + \delta_5 \text{Farmer} + \delta_6 \text{White} + \delta_7 \text{Family16} + \delta_8 \text{East} + \delta_9 \text{Midwest} + \delta_{10} \text{West} + \delta_{11} \text{Rural} + \delta_{12} 1976 + \delta_{13} 1980 + \delta_{14} 1984 + \delta_{15} 1987 + \delta_{16} 1988 + \delta_{17} 1989$

These models are estimated using SAS v. 6.13. To reduce multicollinearity, variables having non-significant parameters in the models are dropped and the equations are re-estimated. Table 4 includes descriptive statistics of the variables. Restricted F tests indicate that variables dropped from the initial specification to reduce multicollinearity do not in aggregate significantly influence variation in the quality of life index. The results from the restricted F-tests are not presented herein but are available from the authors.

The results of the four functional forms using the factor-weighted quality of life indices QLI and QLI' are shown in Tables 5, 6, 7, and 8. For all models, the adjusted R^2 ranges from 0.101 to 0.151. These R^2 values are typical for cross-section studies

explaining variation in attitudes among individuals. Models using a simple summation-weighted quality of life index as a dependent variable have slightly higher adjusted R^2 values. Simple aggregation appears to give satisfactory results. However, normalizing variables about the zero mean and unit variance is recommended as was done for all results in this study.

Coefficients of income, prestige, age, size, gender, employment status, marital status, race, being raised by both a mother and father, residence in the West, and health are significant for all functional forms (Tables 5, 6, 7, 8). For all models the insignificance of coefficients for the year dummy variables indicates that QLI and QLI' are invariant over time. Residence on a farm, in a rural area, and in a specific region (except the West) also had no statistically significant impact on quality of life, other things equal.

Other things being equal, respondents with little education, raised in a single parent family in a small place (city), and in poor health have a lower overall quality of life. In addition, being a male, a nonwhite person, living in the West, and single are associated with a lower overall quality of life. Results in Table 5 indicate that quality of life initially falls and then rises with increasing age, the lowest QLI occurring in the 30-39 year age range.

Judging by the standardized regression coefficients, income, age, and health have the greatest impact on the quality of life. Each standard deviation improvement in the health variable raises the quality of life 0.23 standard deviations according to the results

in Table 5. An increase in occupational prestige and income raises perceived quality of life. The increase in QLI and QLI' as income increases is not constant as demonstrated by the significant INCOME² coefficient. QLI and QLI' increase as income increases but at a decreasing rate, consistent with declining marginal utility of income. The similar standardized parameter estimates for QLI or QLI' suggest that it does not matter which weighting method for quality of life is used. However, the use of factor-weighted aggregation is recommended in subsequent studies if indicator variables other than those in this study are used. Identifying the relationship of the indicator variable components to overall quality of life can be important and assisted by factor analysis.

Evaluation of Marginal Utility

How the perceived quality of life changes as income increases is of special importance in this study. For convenience, the marginal response of the quality of life index to income ($dQLI/dincome$) is called the marginal utility of income (MU) but we recognize that MU is a proxy, an empirical manifestation of an unobservable response of actual utility to changes in income. Equations 3, 4, 5, and 6 show MU derived from the four functional forms of equation results reported in Tables 5 to 8.

The quadratic QLI function (equation 3 and Table 5) exhibits a linear marginal utility curve as apparent from the following first order equations:

$$(7) \quad MU(QLI) = 0.000275 - 1.4274 \times 10^{-9} \text{ Income}$$

$$(8) \quad MU(QLI') = 0.000077 - 3.9230 \times 10^{-10} \text{ Income}$$

A key parameter is the point at which additional income does not add to the quality of life. Solving the above equations for income where $MU = 0$, the results are \$96,328 for equation (7) and \$98,138 for equation (8). When graphed, the MU lines from equations 3 to 6 and Tables 5 to 8 for factor-weighted and summation-weighted aggregations are almost indistinguishable from each other. Because the behavior of MU is influenced little by the method of aggregation, only results for the factor-weighted regressions are shown in Figures 1, 2, 3, and 4. For convenience, the first order equations are normalized to $MU = 1.0$ at the U.S. mean family income (\$32,387: 1986 dollars). Income expressed as a proportion of mean income is graphed on the horizontal axis.

The quadratic form shown in Figure 1 has limitations. Revealed preference theory postulates that people prefer more to less at all income levels, hence marginal utility does not become negative as income becomes large. The persistent effort of affluent individuals to seek even higher income is further, albeit circumstantial, evidence that the marginal utility of income is not negative. We would expect the absolute risk coefficient to decrease, not increase (as implied by the quadratic function) as income becomes large.

Figures 2, 3, and 4 show MU for the Cobb-Douglas, square root, and semilog

equations, respectively. MU derived from these equations are curvilinear but to varying degrees. Table 9 shows MU at various income levels for the four functional forms. At higher income, MU for the square root function is less than for the Cobb-Douglas and semilog equations but is more than for the quadratic function. For measuring MU at higher income levels, the square root function is preferred to the quadratic on conceptual grounds and slightly preferred to the Cobb-Douglas and semilog functions on goodness-of-fit grounds.

One problem with the curvilinear functional forms is that MU unrealistically approaches infinity as income approaches zero. The MU derived from the quadratic function has a more realistic finite value (1.5) at zero income, hence is preferred to the curvilinear specification for measuring MU at low income levels.

Conclusions

A quality of life index, a proxy measure of utility, is constructed by factor-weighted and simple-summation weighted aggregation of socio-psychological measures of well-being. The socio-psychological measures were constructed from quality of life domains taken from selected years of the *General Social Surveys*. The quality of life indices are regressed on income, age, health, and other selected socio-demographic variables using quadratic, Cobb-Douglas, square root, and semilog functional forms.

Regardless of functional form tested and the method of aggregation used to

construct the quality of life index, income, age, and health have the greatest impact on the quality of life. The quality of life is not influenced by the year in which it is measured, suggesting that it is temporally stable. Quality of life as measured here is not much influenced by farm, rural, or regional residence. The method of aggregation used to construct the quality of life index does not greatly influence the measured effect of the selected independent variables on the quality of life. However, normalization of indicator variables to mean zero and variance 1.0 is recommended.

The quadratic function showed the best fit in explaining the variability of the quality of life index. The low R^2 values found herein are not unusual, indicate that much variability in the quality of life is unique to individuals, and indicate that our results are better suited to predict group rather than individual well-being.

The quadratic function has the best fit as measured by R^2 , but is theoretically implausible for high income levels. The Cobb-Douglas, square root, and semilog functions show theoretically plausible MU curves for higher income levels but unrealistically assume infinite utility from the first dollar of income. The degree of MU decline in response to increased income levels is greatest for the square root function and is smallest for the Cobb-Douglas function. Measured by goodness of fit (excluding the quadratic), the square root function is slightly preferred to measure MU at higher income levels. It is also attractive in ranking between the level of MU predicted by the quadratic function on the one hand and the Cobb-Douglas and semi-log functions on the other hand. One option for practitioners computing the benefit-cost ratio for a

public program, project, or policy using results of this study is to weight dollars by income groups with MUs from the quadratic function for income below the mean and from the square root function for income above the mean.

Table 3. Definition of Independent Variables.

Independent	
Variable	Description
Income	Family income in 1986 constant dollars. Income is a continuous variable constructed from mid-range point estimates of 21 family income ranges.
Ageclass	10-19 years = 1 20-29 years = 2 30-39 years = 3 40-49 years = 4 50-59 years = 5 60-69 years = 6 70-79 years = 7 80+ years = 8 No answer, don't know = 4
Prestige	Hodge, Seigel, Rossi prestige scale coded from 1 for lowest prestige occupation to 8 for highest prestige occupation.
Education	Highest grade completed, in actual years of schooling No answer, don't know = 8
Size	Size of Place - This code is the population to the nearest 1,000 of the smallest civil division listed by the U.S. Census (city, town, other incorporated area over 1,000 in population, township, division, etc.)
Health	Would you say your own health in general, is excellent, good, fair or poor? Excellent = 1 Good = 2 Fair = 3 Poor = 4 No answer, don't know = 5

Fair = 3

Poor = 4

Don't know, no answer = 2

Male Dummy variable: Male =1, Female = 0

Unemployed Dummy variable: Unemployed = 1, Other = 0

Married Dummy variable: Married = 1, Other = 0

Farmer Dummy variable: Farmers (owner, operator, tenant,
manager) and Farm Laborers = 1
Others = 0

Family16 Dummy variable: Were you living with
both you own mother
and your own father
around the time you
were 16?
Yes = 1, No = 0

White Dummy variable: A variable indicating race. White = 1, Others = 0

East Dummy Variable: New England = 1

		Middle Atlantic = 1
		Other = 0
Midwest	Dummy Variable:	East North Central = 1
		West North Central = 1
		Other = 0
West	Dummy Variable:	Mountain = 1
		Pacific = 1
		Other = 0
South	Dummy Variable:	South Atlantic = 1
		East South Central = 1
		West South Central = 1
		Other = 0
Rural	Dummy Variable:	Rural = 1, other = 0
		(see classification below - rural taken from Place Size = 9 or 10.
Size	(XNORCSIZE) - Coded from 1 to 10 with largest to smallest size of place of community residence.	
		Central city of over 250,000 population = 1
		Medium size central city of 50,000 to 250,000 = 2

An incorporated area less than 2,500 or an unincorporated area of 1,000 to 2,499 residents
= 9

Open country within a larger civil division such as a township = 10

Year 0-1 Dummy Variables

1976	Dummy Variable: 1976 = 1, Other = 0
1980	Dummy Variable: 1980 = 1, Other = 0
1984	Dummy Variable: 1984 = 1, Other = 0
1987	Dummy Variable: 1987 = 1, Other = 0
1988	Dummy Variable: 1988 = 1, Other = 0
1989	Dummy Variable: 1989 = 1, Other = 0
1990	Dummy Variable: 1990 = 1, Other = 0 (omitted in equation to avoid singularity)

QLI'	40.912	10.885	0.01	71.4114759

Source: Data from the *General Social Surveys*.

Note: Sample Size is 5,259

QLI is the factor weighted quality of life index.

QLI' is the summation aggregated quality of life index.
